Astrophysical limits on light NMSSM neutralinosDaniel Albornoz Vásquez,¹ Geneviève Bélanger,¹ and Céline Boehm^{1,2}¹*LAPTH, U. de Savoie, CNRS, BP 110, 74941 Annecy-Le-Vieux, France*²*IPPP, Ogden Centre, Durham University, Durham, United Kingdom*

(Received 4 August 2011; published 4 November 2011)

It was recently shown that light LSP neutralinos could be found in the framework of the Next-to-Minimal Supersymmetric Standard Model (NMSSM). These candidates would escape known particle physics constraints even though they are relatively light. We now investigate the astrophysical limits which can be set on these particles. We show, in particular, that the Fermi observation of dwarf spheroidal galaxies enable to constrain the parameter space associated with these candidates. Combined with the XENON100 experimental limits, our results illustrate the complementarity between direct and indirect searches for dark matter. Yet, our findings also suggest that probing light neutralinos in the Next-to-Minimal Supersymmetric Standard Model (NMSSM) scenario will be very difficult because the sensitivity of both dark matter direct and indirect detection experiments would have to be improved by at least six orders of magnitude compared to present values in order to explore the entire parameter space. Finally, we show that the parameter space compatible with the CoGeNT signal (albeit disfavored by the XENON100 limit) is not excluded by gamma nor radio observations.

I. INTRODUCTION

After several decades devoted to dark matter searches in underground, collider and spatial experiments, we are finally reaching an important cross road. Now that LHC is running, the Fermi and Planck experiments are delivering data and direct detection experiments have reached the level of sensitivity required to probe dark matter particles in the GeV–TeV range, we expect important developments in the dark matter field. In particular, it is likely that we obtain enough information in the next few years to determine whether supersymmetry manifests itself at the weak scale or not and, hence, whether neutralinos can constitute the dark matter.

Until then, elucidating the nature of dark matter remains challenging. While ongoing experimental efforts try to close down the possible dark matter mass range, several dark matter direct detection experiments have announced events or signals which could point towards the existence of relatively light particles [1–3]. Although these seem also compatible with background expectations, these claims have revived the theoretical interest for candidates in the 1–10 GeV mass range and encouraged experiments to investigate the low energy range despite the lack of sensitivity at small recoil energies.

From a theoretical point of view, motivating candidates in this mass range is not an easy task. For example, the lowest neutralino mass in the Minimal Supersymmetric Standard Model (MSSM) (with common slepton and squark masses and unification of the gluino and wino masses) now appears to be above 15 GeV [4,5]. Relaxing the universality condition, scenarios where neutralinos could be below this value were found [6–9], nevertheless, the low mass range appears to be both fine-tuned and

challenged by direct detection and Higgs searches at colliders.¹ In view of these results, other candidates were investigated, in particular, those in extensions of the MSSM such as the neutralino in the Next-to-Minimal Supersymmetric Standard Model (NMSSM) [11–18], in the MSSM with an extended Higgs sector [19] or the right-handed sneutrino in supersymmetric extensions [20,21].

In a previous study, we explored the parameter space of the NMSSM and demonstrated that NMSSM neutralinos could be very light [4]. In particular, we found that many points with a LSP mass between 1 and 15 GeV were actually compatible with recent particle physics constraints. Some of these points satisfied the direct detection exclusion limits while others were compatible with the possible signals. In this case, the large direct detection cross section is due to the exchange of a light scalar [11]. Here, we investigate whether these scenarios respect the most recent astrophysical limits since light (1–15 GeV) particles could overproduce the radio emission in the Milky Way (MW) and in galaxy clusters [22,23], gamma rays in dwarf spheroidal (dSph) galaxies [24] and antiprotons in the Milky Way [18,25]. The indirect signatures in gamma rays and antimatter were investigated in [26] for neutralinos lighter than 100 GeV in the NMSSM. Neutralino signals from neutrino capture in the Sun and the Earth were analyzed as well. Prospects for detection in all channels were shown to be more favorable for neutralinos near 80 GeV. Here, with a dedicated scan of the parameter space of the NMSSM with neutralinos lighter

¹Neutralinos lighter than 1 GeV have been shown to satisfy collider, astrophysical and cosmological constraints [10] but we do not consider these cases.

than 15 GeV, we show that some scenarios benefit from an enhanced annihilation cross section and are therefore constrained by recent measurements of gamma rays in dSph galaxies.

In Sec. II, we recall the parameter space associated with light NMSSM neutralinos (before applying the astrophysical and direct detection limits). We show, in particular, that some points have a very large annihilation cross section at small dark matter velocity despite a non-negligible relic density. In Sec. III, we show how astrophysical and experimental limits cut into the parameter space, thus demonstrating the complementarity between direct and indirect detection searches. In Sec. IV, we estimate the radio flux expected for benchmark points, selected so as to evade the Fermi and direct detection limits. We conclude in Sec. V.

II. NEUTRALINO ANNIHILATION IN THE NMSSM

In this section, we delineate the parameter space associated with light NMSSM neutralinos and compute the dominant branching ratios. For this purpose, we consider thermal candidates and require that their energy density today is either equal to (or smaller than) the observed dark matter abundance, that is $\Omega_{\text{WMAP}} h^2 > \Omega_\chi h^2 > 10\% \Omega_{\text{WMAP}} h^2$ with $\Omega_{\text{WMAP}} h^2 = 0.1131 \pm 0.0034$ [27]. This basically constrains the total annihilation cross section of neutralinos in the primordial Universe and rules out part of the parameter space. We also impose constraints from new particle searches at colliders, from B-physics observables and from the muon anomalous magnetic moment as detailed in [4].

Once we obtained the configurations which satisfy all these constraints, we can predict the energy spectrum of photons in the galaxy and dSph as well as the flux of cosmic rays in the MW. The comparison of the spin-independent cross section with the limits from CDMS [3] and XENON100 [28] will enable us to set additional constraints. In view of the tension at low dark matter mass between the results from the XENON, CDMS, CoGeNT [1] and DAMA/LIBRA [2] experiments, we will also investigate whether some scenarios can fall into the low mass and large cross section region or not.

To perform this analysis, we have used the same Markov Chain Monte-Carlo code presented in [4] based on the NMSSMTools package [29] embedded in micrOMEGAs [30]. Dark matter observables were computed with micrOMEGAs [31,32].

A. The model

The NMSSM is a simple extension of the MSSM that contains an additional gauge singlet superfield. The VeV of this singlet induces an effective μ term that is naturally of the order of the electroweak scale, thus providing a solution to the naturalness problem [33]. The model contains

one additional neutralino state, the singlino, as well as three scalar (H_1, H_2, H_3) and two pseudoscalar (A_1, A_2) Higgs bosons. An important feature of the model is that the singlet fields can be very light and escape the LEP bounds. This is because these fields mostly decouple from the SM fields [33]. This opens up the possibility for new annihilation mechanisms for light neutralinos, in particular, through the exchange of light Higgs singlets as well as into light Higgs singlets [30]. The model that we consider has input parameters which are defined at the weak scale. The free parameters are taken to be the gaugino masses $M_1, M_2 = M_3/3$, the Higgs sector parameters $\mu, \tan\beta, \lambda, \kappa, A_\lambda, A_\kappa$, a common mass for the sleptons $m_{\tilde{l}}$ and the squarks $m_{\tilde{q}}$ as well as only one nonzero trilinear coupling, A_t , for more details see [4]. We only consider scenarios with a neutralino LSP lighter than 15 GeV.

B. Branching ratios in the early Universe

We start by computing the relic density for each candidate. The main assumption in these calculations is the conventional freeze-out mechanism. As shown in Fig. 1, we have found many points with a relic density in the Wilkinson Microwave Anisotropy Probe (WMAP) range. Hence, although the candidates that we are interested in are light, many have an acceptable relic density. In what follows, we also include the points with a smaller relic density even though they can only partially contribute to the dark matter.

We can now determine the Branching Ratios (BR) associated with the different final states. The results are displayed in Fig. 2. The dominant annihilation channel is either into Higgs pairs, $H_1 H_1$ and $A_1 A_1$, or into fermion pairs. We did not find any configurations with $H_1 A_1$ in the final state. This would require that both the scalar and pseudoscalar be very light, a solution which requires fine-tuning the model parameters especially when requiring a light neutralino that satisfies the WMAP upper limit.

FIG. 1 (color online). Relic density of light NMSSM neutralinos, the darker the dot the larger the likelihood.

FIG. 2 (color online). Branching ratios associated with neutralino pair annihilations in the early Universe. The color code is associated with the constraints from dSph (medium grey) and direct detection (light grey), see Sec. III.

For fermionic modes, the dominant channel is determined by the heaviest kinematically accessible fermion. When the mass of the neutralino is smaller than 1.7 GeV, the only possible final states are into light quarks $s\bar{s}$ and $c\bar{c}$. If the neutralino mass is larger than 1.7 GeV but smaller than 4.2 GeV (m_b), the dominant channel is $\tau\bar{\tau}$ at 90% to 100%. Above the b mass, the dominant fermionic final state is usually $b\bar{b}$. However, the associated branching ratio spans from below 1% to 100% as the Higgs mode can also contribute significantly. Hence, for neutralino masses above the b -quark mass, one expects also annihilations into $H_1 H_1$, $A_1 A_1$ as well as some contribution from $\tau\bar{\tau}$ and $c\bar{c}$.

C. Branching ratios in Milky Way and dwarf spheroidal galaxies

We can now compute the annihilation cross section and branching ratios in the MW and dwarf spheroidal galaxies. In effect, this is equivalent to studying the impact of the dark matter velocity. To take into account the fact that neutralinos may not be responsible for all of the dark matter in the universe and therefore that the halo may not be totally composed of neutralinos, we introduce the parameter

$$\xi = 1 \quad \text{if} \quad \Omega_\chi h^2 \geq \Omega_{\text{WMAP}} h^2 = \Omega_\chi h^2 / \Omega_{\text{WMAP}} h^2 \quad (1)$$

otherwise,

where Ωh^2_{WMAP} corresponds to the lower value of the WMAP measurement. In what follows, we will always rescale the local neutralino density by the factor, $\rho_{\chi_0} = \xi \rho_{\text{DM}}$.

The total annihilation cross section spans several orders of magnitude as displayed in Fig. 3. In some cases, it can be strongly enhanced with respect to its value in the primordial Universe. This "boost" can occur when the annihilation proceeds through a s -channel exchange of a pseudoscalar Higgs particle near resonance, the cross section is then sensitive to the thermal kinetic energy: at small velocities, one gets the full resonance enhancement while at $v \sim c$, one only catches the tail of the resonance [34,35].

The associated cross section is proportional to

$$v\sigma(v) \propto \frac{1}{(s - m_A^2)^2 + \Gamma_A^2 m_A^2} = \frac{1}{16m_\chi^4} \frac{1}{(v^2/4 + \Delta)^2 + \Gamma_A^2 (1 - \Delta)/4m_\chi^2}, \quad (2)$$

where $\Delta = 1 - m_A^2/4m_\chi^2$, m_A , Γ_A the pseudoscalar mass and width and v the relative neutralino velocity. At $v \rightarrow 0$, it is strongly enhanced as compared to its value at freeze-out for $\Delta, \Gamma_A \ll 1$.

To give a more quantitative estimate of this effect, let us consider one allowed scenario with $m_\chi = 10.08$ GeV, $m_{A_1} = 20.12$ GeV, $\Gamma = 1.1 \times 10^{-4}$ GeV and compute the ratio of the thermally averaged cross section at a given temperature, $\langle\sigma v\rangle(T)$ to the value at a typical freeze-out temperature, $\langle\sigma v\rangle(T = m/20)$. The enhancement factor reaches two orders of magnitude and depends mostly on Δ since the term in Γ_A in Eq. (2) is negligible. A small

FIG. 3 (color online). Rescaled neutralino annihilation cross section in the Galaxy vs the neutralino mass, the points which overpredict the gamma-ray flux in dSph are in medium grey, see Sec. III.

FIG. 4 (color online). Ratio of $\langle\sigma v\rangle$ to $\langle\sigma v\rangle(T = m/20)$ as a function of the temperature.

variation in Δ can lead to an even larger enhancement factor, see Fig. 4 where the enhancement factor is displayed for different values of Δ .

As a result, we find that the neutralino annihilation branching ratios in the MW or dSph differ from those found in the early Universe. Our results are summarized in Fig. 5, where we only display the final states which opened up at low velocities. The $A_1 A_1$ and $H_1 H_1$ are no longer possible final states because the associated cross sections are both suppressed. On the other hand, the branching ratios for the $c\bar{c}$ and $\tau\bar{\tau}$ now reach unity for many points where $m_\chi > m_c$ and $m_\chi > m_\tau$, respectively.

Many scenarios have indeed a very small annihilation cross section in dwarf galaxies due to a p -wave suppression factor. This affects, in particular, the annihilation processes which were dominated in the early Universe by

FIG. 5 (color online). Branching ratios associated with neutralino pair annihilations at low velocities (same color code as Fig. 2.).

a H_1 resonance decaying into Fermion pairs as well as annihilation into light Higgs final states through the t and u channel neutralino exchange. For these configurations, channels such as the t -channel sFermion exchange, which were subdominant in the early Universe, become important when $v \rightarrow 0$.

In principle, we can make generic predictions for all the configurations with a $\text{BR} = 1$ for a given channel since the annihilation cross section can be factorized. However, most of the dark matter scenarios that we have found have a mixture of final states. Hence, in the following, we will compute individually the gamma and cosmic ray fluxes for each point considered.

III. ASTROPHYSICAL LIMITS

We can now investigate the astrophysical limits which apply to light neutralinos.

A. Gamma rays in dSph

Objects such as dSph are meant to be dark-matter dominated and represent therefore in principle a good target for dark matter searches [24,36,37]. Dark matter annihilations are expected to produce quarks and/or taus in the final state which, in turn after hadronization, produce gamma rays. Photons can also be produced directly as radiation from an internal line or from a final state. Finally, it is also possible that neutralino annihilate directly into photon pairs through a loop-induced process [26,38].

The flux of gamma rays originating from dark matter annihilation into all SM final states, is thus given by

$$\frac{d\phi_\gamma(E)}{dE} = \frac{1}{2} \frac{1}{4\pi} \left(\frac{(\sigma v)_{\text{tot}}}{m_{\chi_0}} \right)^2 \sum_i \text{BR}_i \frac{dN_i}{dE} \xi^2 \times \int dl(\psi) \rho_{\text{DM}}^2[l(\psi)], \quad (3)$$

where $(\sigma v)_{\text{tot}}$ is the total annihilation cross section and BR_i is the fraction into a given SM final state i , ρ_{DM} is the dark matter energy density, dN_i/dE is the number of photons produced after hadronization (or radiation even though this process is generally subdominant) in terms of the energy E , $l(\psi)$ is the line of sight in the ψ direction. The factor $1/2$ accounts for the Majorana nature of the neutralino.

This flux has to be integrated over the Fermi angular resolution. For an angular region of diameter 0.5° , as considered by the Fermi experiment [39], one is not sensitive to the inner slope of the dark matter halo. Hence, we can safely consider a NFW dark matter halo profile. The value of the integral along the line of sight and averaged over the resolution is taken from Table 4 in [39]. The energy-dependent part of the differential flux is then computed with micrOMEGAs and integrated from $0.1 \text{ GeV} < E < m_{\chi_1^0}$.

For each point found by our MCMC, we have computed the gamma-ray flux expected in the eight dwarfs

FIG. 6 (color online). Predicted photon flux as a function of the LSP mass. The horizontal lines correspond to the Fermi limit including the 1σ error bars in the integral over the DM density distribution. Points excluded by XENON100 are in light grey.

considered by the Fermi experiment. We then compare this value with the Fermi-LAT 95% limits [39]. Our results are displayed in Fig. 6 for Draco, which gives the most sensitive limits. As expected, excluded models are those with the largest annihilation cross section (irrespective of the dominant annihilation channel, see also Fig. 3) and for which the mass difference between the LSP and the pseudoscalar involves a fair amount of fine-tuning. The predictions for the photon flux for the scenarios with a relic density within the WMAP range, span the whole range of values displayed in Fig. 6.

Note that the exclusion limit varies only slightly with the mass. Basically, it corresponds to $\xi^2 \sigma v / m_{\chi_1^0}^2 \geq 2\text{--}5 \times 10^{-29} \text{ cm}^3 \text{s}^{-1} \text{GeV}^{-2}$. Also, the criterion for exclusion is based on a comparison of the computed flux with the Draco limit taking into account the 1σ error bars in the

integral over the DM density distribution. Thus, it is a conservative exclusion criterion. We have further checked that the photon flux from the loop-induced process, was below the Fermi LAT reach for the points that satisfied the Draco limit [38]. However, many points excluded by Draco could also be excluded by other astrophysical observations (including by the flux of antiprotons measured at Earth position). The implications for the Higgs spectrum will be discussed in Sec. III D.

B. Antiproton and positron fluxes in the Milky Way

We can now investigate the cosmic ray production in the MW. Calculations are similar to gamma rays except that now we focus on positron and antiproton production. We also expect that the best signals are associated with the largest annihilation cross section.

Since the limits from dSphs are already very constraining, we shall consider other astrophysical bounds as a complementary tool and thus apply them only to the scenarios which survived the Fermi constraints. For this purpose, we group all the scenarios in bins of 1 GeV for neutralino masses ranging from 1 to 15 GeV and, for each of the 14 bins, we select the point with the maximum value for $\xi^2 \sigma v / m_{\chi_1^0}^2$ and with a good likelihood (defined as $Q > 0.32 Q_{\text{max}}$) and which, yet, is safe with respect to the Draco limits. This leads to 14 benchmark points. The dominant annihilation channel for all of them is into $b\bar{b}$ for $m_{\chi_1^0} > 4.2$ GeV and into $\tau\bar{\tau}$ otherwise. The benchmarks are listed in Table I. Assuming that only one annihilation channel dominates for each neutralino mass, the signatures in photons, antiprotons, and positrons will be directly proportional to the neutralino annihilation cross section, hence the best signal is found for the maximum value of $\xi^2 \sigma v$ for a given LSP mass. For neutralino masses below the b -quark production threshold, there could be

more than one annihilation channel, however, all points with large cross sections are dominated by the τ final state.

The results for the antiproton fluxes are displayed in Fig. 7 and compared to the background spectrum taken from the approximate analytical formulas in Ref. [40]. This background by itself provides a good fit to the data. The fluxes computed are close to one order of magnitude below the background from secondaries at energies below ≈ 2 GeV and drop rapidly at higher energies. We therefore conclude that one cannot further constrain these scenarios by measuring the antiproton flux, as the uncertainty in the background calculation (which exceeds 10%) is always larger than the signal.

Note that to compute these fluxes we have set the propagation parameters to the default values in micrOMEGAs, i.e. the MED set of parameters, see Ref. [41]. For a different set of propagation parameters, the expected fluxes can increase. Indeed, we find that the fluxes reach at most the background level with the MAX set of propagation parameters (corresponding to a larger diffusive zone), see Ref. [41,42].

For completeness, we have also computed the positron fluxes for the 14 benchmark points, using the MED propagation parameter set [42]. The fluxes are always at least two orders of magnitude below the background [43], see Fig. 8. This was to be expected since the scenarios that we have selected predict dominant quark final states; hence, a better signature in antiprotons than in positrons. Note that the $\tau\bar{\tau}$ channel, which leads to a hard positron spectrum, is dominant either at very low masses or when the cross section is very small.

C. Comparison with direct detection

In the light neutralino scenarios, there is a good complementarity between gamma-ray searches and direct

FIG. 7 (color online). Cosmic ray predictions for the antiproton spectra for 13 benchmark points in Table I. The first point in this table is ignored as it is too light to give antiprotons. The maximal energy for each spectrum corresponds to the neutralino mass. The background from secondaries [40] (dash) is also displayed.

FIG. 8 (color online). Predictions for the positron spectra as compared to the background [43] (dash) for 14 benchmark points in Table I. The maximal energy for each spectrum corresponds to the neutralino mass.

searches. Indeed, many scenarios which predict a spin-independent cross section below the XENON100 exclusion curve overpredict the gamma-ray flux in dSph galaxies, see Fig. 9. This is also illustrated in the correlation plot displayed in upper panel of Fig. 10, where we show the gamma-ray flux as a function of the spin-independent cross section. Clearly, the Fermi dSph limits constrain scenarios where the spin-independent cross section is smaller than the latest XENON100 limit, while the XENON100 limits exclude points where the gamma-ray flux in dSph is not yet accessible by the Fermi searches. In the framework of the NMSSM, this complementarity is directly connected to the light Higgs spectrum as discussed in the next subsection.

If we now remove the points which do not have the correct abundance today and exclude the points which

FIG. 9 (color online). Spin-independent cross section vs the neutralino mass. The points which overpredict the gamma-ray flux in dSph are in medium grey.

FIG. 10 (color online). Correlation between the gamma-ray flux and spin-independent cross section of NMSSM neutralinos. Top: all points are included. The light grey points correspond to scenarios with a too large spin-independent cross section. The dashed line corresponds to the Fermi limit for the Draco dSph. Bottom: all points overpredicting the gamma-ray flux or with a too large spin-independent cross section and which do not completely explain the dark matter today have been removed.

produce too many gamma rays in Draco and non-observed events in XENON100 (see Fig. 10, lower panel), we obtain that, statistically, light neutralinos are likely to produce $[10^{-14}, 10^{-10}] \gamma/\text{cm}^2/\text{s}$ and have a spin-independent cross section of $[10^{-48}, 10^{-44}] \text{cm}^2$.

We have also computed the gamma-ray flux for points which are in the region favored by the CoGeNT experiment [1]. All these points lie in the region excluded by Xenon100. However, since CoGeNT claims detection at 2σ of an annual modulation signal [44], it is worth investigating the astrophysical limits for such candidates.

Since we have demonstrated that indirect and direct detection experiments were probing different regions of the parameter space and these candidates are within XENON100 sensitivity, we do not expect that they produce large gamma-ray and cosmic-ray fluxes. However, to check this statement, we shall consider three benchmark points (cf Table II).

For these points, we found $\xi^2 \sigma v / m_\chi^2 \leq 6 \times 10^{-31} \text{cm}^3 \text{s}^{-1} \text{GeV}^{-2}$ which is one or two orders of magnitude below the Draco limit in Sec. III A. Hence, it seems that NMSSM neutralinos in the CoGeNT region are not excluded by the indirect detection limits for the moment.

This is an important point nevertheless. Indeed, it will be challenging for both dark matter direct and indirect detection experiments to reach the level of sensitivity which is required to completely probe the region of the parameter space with light neutralinos. In addition, new sources of background (such as the neutrino background for the direct detection experiments) may also weaken the analysis.

D. Implication for particle physics

In the previous subsections, we have demonstrated that the Fermi dSph limits were setting stringent limits on the NMSSM parameter space and were complementary to dark matter direct detection searches. We can now examine the impact of these limits on the Higgs sector and on B -physics observables.

Efficient neutralino annihilation in the early Universe requires at least one light Higgs ($m_{H_1}, m_{A_1} < 30 \text{ GeV}$ for $m_{\tilde{\chi}} < 15 \text{ GeV}$) as illustrated in Fig. 11. Astrophysical limits then apply in two distinct regions of the $m_{A_1} - m_{H_1}$ plane. The first region corresponds to a light H_1 ($m_{H_1} \in [1, 10] \text{ GeV}$) and to heavier A_1 (with $m_{A_1} \in [10, 1000] \text{ GeV}$). In this region, the spin-independent cross section can become very large, which is in conflict with XENON100 data (in yellow in Fig. 11). Indeed, as can be seen in Fig. 12, larger spin-independent cross sections are found for light H_1 . This is because the scalar exchange

TABLE II. Three examples of NMSSM points falling in the CoGeNT contour [1] in the $\xi \sigma^{\text{SI}}$ vs $m_{\chi_1^0}$ plane. For all of them we have set $M_3 = 3 \times M_2$ and $A_b = A_\tau = 0$. All quantities are expressed in GeV units.

FIG. 11 (color online). Correlation in the (m_{A_1}, m_{H_1}) plane. All the safe configurations (dark grey) as well as the excluded points by XENON100 (light grey) and dSph (medium grey) are displayed.

FIG. 12 (color online). Spin-independent cross section in terms of m_{H_1} , same color code as Fig. 11.

contribution to the cross section goes as $1/m_{H_1}^4$. Note that because sufficiently large couplings of the light Higgs to the LSP and to quarks in the nucleon are necessary to have a large SI cross section [4], many points with light H_1 are not excluded. The second region corresponds to a relatively light A_1 ($m_{A_1} \in [10, 30]$ GeV) and $m_{H_1} \in [20, 100]$ GeV. Here, the neutralino pair annihilations (which proceed through the exchange of an A_1 in the s -channel) become singular when $v_{dm} \rightarrow 0$ and $1 - m_{A_1}/2m_\chi \ll 1$ and thus can produce too many gamma rays in dwarf galaxies (see points in red in Fig. 12).

The observables in the B -sector have been used to constrain the parameter space. The LHCb experiment, which is now taking data, will measure these observables with increased precision, it is therefore interesting to examine whether this will probe further our scenarios. For example, the branching ratio for $B_s \rightarrow \mu^+ \mu^-$ is expected to be powerful in probing scenarios with a light doublet Higgs

FIG. 13 (color online). Predictions for the branching ratio $B(B_s \rightarrow \mu^+ \mu^-)$ in terms of m_{χ_1} together with the Tevatron limit and the LHCb projected limit, same color code as Fig. 11.

and large values of $\tan\beta$. Only a fraction of our scenarios have such characteristics. The predictions for $B(B_s \rightarrow \mu^+ \mu^-)$ are displayed in Fig. 13 together with the expected limit of LHCb with $\mathcal{L} = 1 \text{ fb}^{-1}$ [45]. A signal is expected only for a small fraction of the scenarios while in some cases the predictions are suppressed as compared to the SM expectation ($B(B_s \rightarrow \mu^+ \mu^-) = 3.6 \pm 0.4 \times 10^{-9}$) [46]. This implies that light neutralino scenarios cannot be probed entirely with this observable.

IV. RADIO EMISSION IN THE GALACTIC CENTER AND THE COMA CLUSTER

Since light particles eventually produce electrons in the MW, one expects a significant radio emission in the galactic center as well as in galaxy clusters as first pointed out in [22] and discussed further in, e.g., Ref. [23,47–50].

This is true, in particular, for the points with large cross sections at $v \rightarrow 0$ and $\xi \simeq 1$ (i.e., canonical values in the primordial Universe). Since these points have been already excluded by using the Fermi dSph limits, we shall rather concentrate on the part of the parameter space that is left after applying the gamma-ray constraint. We thus compute the radio flux expected for the benchmark points displayed in Table I.

We repeat the same calculations as in Ref. [23], where we assume the MED set of propagation parameters and set the magnetic field, B , to $20 \mu\text{G}$. This value is slightly higher than that derived in [51] for very small scales but it is still conservative enough with respect to the very large value generally considered for the magnetic field in the galactic center. Choosing the MAX set of propagation parameter would in fact decrease the intensity of the radio emission expected in the galactic center but it would also lead to a broader radio emission in the Galaxy. On the contrary, for the MIN set of propagation parameters, one expects a brighter emission in the galactic center which should be easier to constrain in principle.

We focus on one radio frequency, namely, 330 MHz where the emission is about 360 Jy (for an angular resolution of $7'$) and compute the ratio R of the “dark” emissivity to the observation at this frequency in the galactic center, for each of the points mentioned above. The results are displayed in Table I, in the last column. We find that all the benchmark points have a negligible radio flux. This can be explained by the fact that, in all these scenarios, the total number of electron produced in the 0.5 to 15 GeV range is about unity (a minimal injection energy of 1 GeV is required for $B = 20 \mu\text{G}$ to produce synchrotron emission at 330 MHz). Indeed, all the benchmark points annihilate preferably into b or τ -pairs. This leads to a very small number of electrons per energy unit for $E > 1$ GeV.

Note that the determination of the magnetic field value is of particular importance because it changes the synchrotron emission (hence the radio predictions) and the losses. However, it also determines other possible signatures such as an anomalous submillimeter emission in the Galaxy which could contribute as a new source of foreground in Cosmological Microwave Background studies. For example, to get a signal at 33 GHz (relevant for both WMAP and Planck) from a 10 GeV dark matter particle, the magnetic field should be greater than $25 \mu\text{G}$ [52]. If such a value is indeed attained in the galactic center or in the outer parts, one can hope to correlate “dark” radio emission with WMAP and Planck observations, e.g., [52–55].

One can also estimate the radio emission in clusters of galaxies to determine whether light dark-matter particles are potentially constrained by radio observations in these objects [22,23,47]. To compute the flux, we consider the Coma cluster and extend the procedure described in [22,23] to account for the energy distribution of electrons. We assume a NFW profile [56] with $\rho_0 = 4.4 \cdot 10^{-2} \text{ GeV}/\text{cm}^3$, $r_s = 400 \text{ kpc}$, a detector angular resolution of 1° , a magnetic field of $4.7 \mu\text{G}$, and a density of electrons of $3 \cdot 10^{-3} \text{ cm}^{-3}$.

The results for our benchmark points are displayed in Fig. 14.² Our prediction shows that none of these points are excluded by the observation in the Coma cluster, as expected already from our computations in the galaxy.

These results do not account for substructures. Also, they assume a specific value of the magnetic field. If we increase this value by a significant amount, the radio flux becomes larger and the emission becomes also possible at higher frequencies. For example, increasing the value of the magnetic field up to $12 \mu\text{G}$ increases the radio flux at 4.58 GHz by a factor ~ 4.5 for the last benchmark point (corresponding to a candidate with 14.48 GeV mass). Still, this is not enough to rule out this candidate.

²We have checked that we could recover the results in [47] for a 40 GeV candidate annihilating into a $b\bar{b}$ pair and with the same cross section.

FIG. 14 (color online). Radio flux in the Coma cluster for 13 benchmark points displayed in Table I from the second lightest (left) to the heaviest (right) candidates. The data set are taken from the references in [62].

V. CONCLUSION

In this article, we have investigated the astrophysical limits on light NMSSM neutralinos. We have shown that the Fermi searches for gamma rays from dwarf Spheroidal galaxies set stringent limits on the NMSSM parameter space. In addition, combining these results with indirect and direct detection searches restrict the parameter space even further. Yet light neutralinos are not ruled out.

It may be extremely difficult to completely probe light neutralinos in the forthcoming future. Indeed, this would require an improvement in both direct and indirect detection experiments’ sensitivity by several order of magnitudes while experiments may run into new background sources.

The LHC could nevertheless provide crucial information on the existence and on the spectrum of supersymmetric particles and investigate distinctive signatures involving light neutralinos, for example, invisible decay modes of the Higgs [14]. Furthermore, the mass of a light neutralino, produced in the decay of a selectron, could be determined at a future linear collider, in which case, selectrons have to be light enough to be pair-produced [57]. Light DM particles can also have an impact on the CMB [22,58–60]. In Ref [59,60], it was shown that their annihilation cross section is constrained by WMAP to be around the usual freeze-out cross section unless DM particles annihilate mainly into neutrinos, as in [61] for even lighter DM candidates. However, the Planck satellite should further probe these scenarios by detecting an anomalous synchrotron emission [52]. Nonetheless, at present, our results demonstrate that the complementarity between direct and indirect searches is a reality and a necessity, at least in the framework of supersymmetric scenarios.

ACKNOWLEDGMENTS

G.B. thanks the LPSC for its hospitality. The authors would like to thank David Maurin for information on the flux of antiprotons from secondaries, Guillaume Chalons for computing the gamma-ray line for several of our

scenarios as well as Alexander Pukhov, Joe Silk and Pierre Salati for useful discussions. This work was supported in part by the CNRS-PICS grant “Propagation of low energy positrons.”
